Quantum Emergence from Primordial Potentiality: The Dual-Non-Dual Framework for State Differentiation

D-ND Research Collective

Independent Research

(Dated: February 28, 2026)

We present a closed-system framework for quantum emergence in which a primordial state of indifferentiation — the Null-All state $|NT\rangle$ — undergoes constructive differentiation via an emergence operator $\mathcal{E}$, yielding observable reality as $R(t) = U(t)\mathcal{E}|NT\rangle$. Unlike environmental decoherence, which describes loss of coherence through interaction with external degrees of freedom, our model explains the *construction* of classical structure within a closed ontological system. We define an emergence measure $M(t) = 1-|\langle NT|U(t)\mathcal{E}|NT\rangle|^2$ and establish its asymptotic convergence under specified conditions. Applying the Riemann-Lebesgue lemma within this closed-system ontology, we show that for systems with absolutely continuous spectrum and integrable spectral density, $M(t) \to 1$ (total emergence), and for discrete spectra, the Cesàro mean $\overline{M}$ converges to a well-defined value. We prove that the emergence operator $\mathcal{E}$ is uniquely determined (up to conjugacy) by the evolutionary and autological axioms: $\mathcal{E} = \left(\begin{smallmatrix} 1\&1 \\ 1\&0 \end{smallmatrix}\right)$ with $\det(\mathcal{E}) = -1$ as a theorem and eigenvalues in $\mathbb{Q}(\sqrt{5})$. The asymptotic convergence results employ standard mathematical machinery (Riemann-Lebesgue lemma, Cesàro means); the contribution is the derivation of $\mathcal{E}$ from first principles and the reinterpretation within a constructive, closed-system framework where the continuous spectrum arises from internal structure rather than environmental tracing. These results define an informational *arrow of emergence* — distinct from thermodynamic and gravitational arrows of time — arising purely from the differential structure of the quantum system. We derive the explicit **Hamiltonian decomposition into dual sectors** ($\hat{H}_+$), anti-dual ($\hat{H}_-$), and interaction Hamiltonians, establishing the fundamental quantum dynamics from which emergence arises. We present a **Lindblad master equation for emergence-induced decoherence**, with a phenomenological decoherence rate $\Gamma = \sigma_V^2/\hbar^2 \cdot \langle(\Delta\hat{V}_0)^2\rangle$ motivated by dimensional analysis and Fermi Golden Rule consistency, explaining the arrow of emergence through open-system dynamics in the intrinsic potential landscape. We introduce

a foundational framework based on **six axioms ($\mathbf{A_1}$–$\mathbf{A_5}$ for quantum mechanics, $\mathbf{A_6}$ for cosmological extension)**, grounding the emergence dynamics at both quantum and cosmological scales. We situate the framework relative to Zurek's quantum Darwinism, Penrose's objective reduction, Wheeler's participatory universe, Tononi's integrated information theory, and recent information-geometric approaches to emergent spacetime. We derive the classical limit connecting $M(t)$ to the order parameter $Z(t)$ of an effective Lagrangian theory, derive the cyclic coherence condition $\Omega_{NT} = 2\pi i$ as a motivated conjecture from WKB analysis governing periodic emergence orbits, and propose concrete experimental protocols for circuit QED and trapped-ion systems with quantitative predictions distinguishing D-ND emergence from standard decoherence. —

I. 1. INTRODUCTION

A. 1.1 The Problem: Emergence and Differentiation

A fundamental puzzle at the foundations of physics concerns the origin of differentiation: how does observable classical reality with distinct states and properties emerge from an undifferentiated quantum substrate? The standard narrative appeals to three mechanisms:

1. **Thermodynamic arrow**: The Second Law of Thermodynamics establishes a temporal direction via statistical mechanics, but presupposes an asymmetric initial condition (low entropy) whose origin remains unexplained (Penrose 2004).

2. **Gravitational arrow**: Penrose's gravitational entropy hypothesis connects time asymmetry to black hole formation and gravitational degrees of freedom. However, this mechanism is scale-dependent and confined to gravitational regimes (Penrose 2010).

3. **Quantum decoherence**: Following Zurek (2003, 2009), Joos & Zeh (1985), and Schlosshauer (2004, 2019), environmental interaction causes superposition to collapse into pointer states, explaining the emergence of apparent classical behavior.

Yet decoherence is inherently *destructive* — it describes information loss to the environment, not information creation within a closed system.

All three mechanisms address the *appearance* of classicality or the *loss* of coherence. None directly address the *emergence* of structure and differentiation from an indifferent initial state within a closed system.

B. 1.2 Gap in the Literature

The central gap is this: **decoherence explains the "how" of coherence loss but not the "why" of emergent differentiation.** A superposition $\frac{1}{\sqrt{2}}(|\uparrow\rangle + |\downarrow\rangle)$ exists prior to decoherence; the process suppresses interference between these pre-existing states but does not explain why *these particular states* are distinguished.

More fundamentally, decoherence requires an external environment — it is an *open system* process. Yet the universe as a whole has no external environment. Wheeler's (1989) "it-from-bit" program and the Hartle-Hawking (1983) no-boundary proposal both suggest that any foundational theory of emergence must apply to closed systems. The recent holographic emergence program — from AdS/CFT (Maldacena 1998) through Ryu-Takayanagi (2006) to Van Raamsdonk (2010) — further demonstrates that spacetime itself is not fundamental but emerges from entanglement structure, reinforcing the need for a closed-system emergence mechanism.

C. 1.3 Proposal: Constructive Emergence via $\mathcal{E}$

We propose the **Dual-Non-Dual (D-ND) framework** as a closed-system alternative:

- **Primordial state**: $|NT\rangle$ (Null-All state) represents pure, undifferentiated potentiality — a uniform superposition of all eigenstates.

- **Emergence operator**: $\mathcal{E}$ acts on $|NT\rangle$ constructively, selecting and weighting specific directions in Hilbert space. Unlike environmental interaction, $\mathcal{E}$ is an *intrinsic* feature of the system's ontological structure.

- **Emergence measure**: $M(t) = 1 - |\langle NT|U(t)\mathcal{E}|NT\rangle|^2$ quantifies the degree of differentiation from initial potentiality.

- **Arrow of emergence**: The asymptotic behavior of $M(t)$ establishes a third fundamental arrow — orthogonal to thermodynamic and gravitational arrows — arising from the differential structure of the quantum system.

D. 1.4 Contributions of This Work

1. **Formal framework** with six axioms (A_1–A_5 for quantum mechanics, A_6 for cosmological extension), grounded in the Wheeler-DeWitt equation (Axiom A_4), Lawvere's fixed-point theorem (Axiom A_5), and holographic structure coupling to spacetime geometry (Axiom A_6).

2. **Rigorous asymptotic theorems** with explicit regularity conditions and counterexamples correcting over-claims in preliminary formulations.

3. **Explicit Hamiltonian decomposition into dual ($\hat{H}_+$), anti-dual ($\hat{H}_-$), and interaction sectors**, establishing the fundamental dynamics of the D-ND system.

4. **First-principles derivation of $\mathcal{E}$** (Theorem 3): the emergence operator is uniquely determined by Axioms A_3 + A_5, with $\det(\mathcal{E}) = -1$ as a theorem and eigenvalues in $\mathbb{Q}(\sqrt{5})$.

5. **Information-theoretic characterization** of $\mathcal{E}$ via the maximum entropy principle (Jaynes 1957).

6. **Lindblad master equation for emergence dynamics with quantitative decoherence rate** $\Gamma = \sigma_V^2/\hbar^2 \cdot \langle(\Delta\hat{V}_0)^2\rangle$, explaining non-unitary dynamics through intrinsic potential fluctuations.

7. **Quantum-classical bridge** deriving the effective Lagrangian order parameter $Z(t)$ from the quantum emergence measure $M(t)$.

8. **Computational validation via numerical simulation of** $M(t)$ **trajectories** for $N = 2, 4, 8, 16$, confirming analytical predictions within $\pm 0.5\%$.

9. **Concrete experimental protocols** for circuit QED and trapped-ion systems with quantitative predictions.

10. **Comprehensive comparison** with decoherence, quantum gravity, and information-geometric frameworks.

II. 2. THE DUAL-NON-DUAL FRAMEWORK

A. 2.1 Axioms $\mathbf{A_1}$–$\mathbf{A_6}$ (Revised)

We ground the framework in six foundational axioms, the last of which is a cosmological extension. Axioms A_4 and A_5 have been revised from their preliminary formulations to resolve circularity and self-justification issues respectively. Axiom A_6 extends the framework to cosmological scales.

Axiom $\mathbf{A_1}$ (Intrinsic Duality). Every physical phenomenon admits a decomposition into complementary opposite components, Φ_+ and Φ_-, such that the union $\Phi_+ \cup \Phi_-$ is exhaustive and mutually exclusive in any measurement.

Justification: This formalizes the ubiquity of binary distinctions in quantum mechanics (spin-up/down, particle/antiparticle, localized/delocalized) without commitment to a specific interpretation.

Axiom $\mathbf{A_2}$ (Non-Duality as Indeterminate Superposition). Beneath all dual decompositions exists a primordial undifferentiated state, the Null-All state $|NT\rangle$, in which no duality has actualized:

$$|NT\rangle = \frac{1}{\sqrt{N}} \sum_{n=1}^{N} |n\rangle \tag{1}$$

where $\{|n\rangle\}$ spans the full basis of $\mathcal{H}$, with $N \to \infty$ for infinite-dimensional spaces.

Justification: This state captures "pure potentiality" — it contains all information (uniform superposition) yet distinguishes nothing (no state is privileged). It is the Hilbert space analogue of the Hartle-Hawking no-boundary wave function (Hartle & Hawking 1983).

Axiom $\mathbf{A_3}$ (Evolutionary Input-Output Structure). Every system evolves continuously via input-output cycles coupled through a unitary evolution operator $U(t) = e^{-iHt/\hbar}$:

$$R(t) = U(t)\mathcal{E}|NT\rangle \tag{2}$$

where $R(t)$ is the resultant state and $\mathcal{E}$ is the emergence operator acting at the boundary between non-duality and manifestation.

Axiom $\mathbf{A_4}$ (Relational Dynamics in Timeless Substrate) [Revised]. The total system satisfies the Wheeler-DeWitt constraint (Wheeler 1968):

$$\hat{H}_{\text{tot}}|\Psi\rangle = 0 \tag{3}$$

on the extended Hilbert space $\mathcal{H} = \mathcal{H}_{\text{clock}} \otimes \mathcal{H}_{\text{system}}$. Observable dynamics emerge relationally via the Page-Wootters mechanism (Page & Wootters 1983; Giovannetti, Lloyd & Maccone 2015): the conditional state

$$|\psi(\tau)\rangle = {}_{\text{clock}}\langle\tau|\Psi\rangle \tag{4}$$

yields the effective evolution $R(\tau) = U_{\text{sys}}(\tau)\mathcal{E}|NT\rangle_{\text{sys}}$, where τ is the relational parameter defined by the internal clock subsystem. The parameter t in Axiom A_3 is identified with τ; it is not absolute time but an emergent relational observable.

Justification: This resolves the circularity in preliminary formulations where time was both the object being explained and the parameter used to explain it. The Page-Wootters mechanism demonstrates that evolution emerges from entanglement correlations within a globally timeless state — a result experimentally verified by Moreva et al. (2014). The potential fluctuation equation $\delta V = \hbar\, d\theta/d\tau$ is now defined with respect to the relational parameter τ, not absolute time.

Axiom $\mathbf{A_5}$ (Autological Consistency via Fixed-Point Structure) [Revised]. The system's inferential structure admits a self-referential map $\Phi : \mathcal{S} \to \mathcal{S}$ on the state space of descriptions. By Lawvere's fixed-point theorem (Lawvere 1969), Φ admits at least one fixed point $s^* = \Phi(s^*)$, representing a self-consistent description where the system's state and its description of its own state coincide. This fixed point is inherent in the categorical structure of $\mathcal{S}$ (not reached by iteration), hence the autological closure is mathematically guaranteed.

Justification: This replaces the preliminary assertion of "zero-latency self-reference" with rigorous mathematical grounding. Lawvere's theorem — the categorical generalization unifying Cantor's diagonal argument, G'odel's incompleteness, and Tarski's undefinability (Lawvere 1969) — guarantees the existence of self-consistent fixed points whenever the space of descriptions admits exponential objects and sufficient surjectivity. The "zero latency" is a mathematical property (fixed points exist by structure, not by convergence), not a physical claim about instantaneous signaling.

Operational Form ($R + 1 = R$): The autological fixed-point condition has an elegant operational expression: $R(t + 1) = R(t)$ at the fixed point s^*. This is not a trivial identity but a *convergence criterion*: the proto-axiom that generates each iteration does not change through iteration — it expands to include new dimensions of comprehension while preserving its structure. In the D-ND genesis documents, this condition was expressed as "$R + 1 = R$," meaning that each new resultant is not an update to the previous one but a revelation of what was already contained in it. Formally, this corresponds to the Ba-

nach contraction condition: $\|R(t+1) - R(t)\| \leq \kappa \|R(t) - R(t-1)\|$ with $\kappa < 1$, ensuring convergence to the fixed point $s^* = \Phi(s^*)$ guaranteed by Axiom A_5.

Axiom A_6 (Holographic Manifestation) [Cosmological Extension]. The spacetime geometry $g_{\mu\nu}$ must encode the collapse dynamics of the emergence field. Specifically, any physical metric must satisfy the constraint that its curvature couples to the emergence operator $\mathcal{E}$ through the informational curvature K_{gen}:

$$R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu} + \Lambda g_{\mu\nu} = 8\pi G \cdot T^{\text{info}}_{\mu\nu}[\mathcal{E}, K_{\text{gen}}] \tag{5}$$

where $T^{\text{info}}_{\mu\nu}$ is the informational energy-momentum tensor derived from the spatial integral of K_{gen} acting on the emergent state $R(t)$.

Justification: This axiom extends the framework to cosmological scales, asserting that geometry is not independent of emergence but structurally coupled to it. It is the D-ND counterpart of the holographic principle (Ryu & Takayanagi 2006): just as the Ryu-Takayanagi formula connects bulk geometry to boundary entanglement entropy, Axiom A_6 connects spacetime curvature to the emergence dynamics of $\mathcal{E}$. This axiom is invoked primarily in Paper E (Cosmological Extension) and is not required for the quantum-mechanical results of §§ 2–5. It corresponds to the "P4" axiom in Paper E's extended cosmological axiom system.

Note: Axiom A_6 is a cosmological extension axiom — it is not required for the quantum emergence results (§§ 2–5) or the quantum-classical bridge (§ 5), which depend only on A_1–A_5. It becomes necessary when coupling emergence dynamics to spacetime geometry at cosmological scales (Paper E).

B. 2.2 The Null-All State $|NT\rangle$

The Null-All state is the mathematical embodiment of non-duality: maximal superposition containing all possibilities with equal weight.

Properties:

1. **Completeness**: $|NT\rangle$ spans the entire Hilbert space uniformly.

2. **Normalization**: $\langle NT|NT\rangle = 1$ by construction.

3. **Observable expectation**: For any observable $\hat{O}$, $\langle NT|\hat{O}|NT\rangle = \frac{1}{N}\mathrm{Tr}[\hat{O}]$.

4. **Maximal von Neumann entropy**: The pure-state density matrix $\rho_{NT} = |NT\rangle\langle NT|$ satisfies $S_{\mathrm{vN}}(\rho_{NT}) = 0$ (pure state), but the reduced density matrix over any subsystem is maximally mixed.

5. **Basis independence**: The expectation value $\langle NT|\hat{O}|NT\rangle = \mathrm{Tr}[\hat{O}]/N$ is independent of the choice of basis, reflecting the absence of preferred measurement direction.

Remark (Mathematical Status of $|NT\rangle$): We emphasize that $|NT\rangle$ is a standard quantum state — a uniform superposition — and makes no claim to intrinsic ontological privilege. Any state $|\psi_0\rangle$ could serve as the initial condition; the choice of $|NT\rangle$ is motivated by (1) maximal symmetry (basis independence, Property 5), (2) analogy with the Hartle-Hawking no-boundary state, and (3) the informational principle that the least-committed initial state should be the starting point for emergence. The novelty of the framework lies not in $|NT\rangle$ itself but in the *emergence operator* $\mathcal{E}$ and the *measure* $M(t)$ that track how differentiation proceeds from any maximally symmetric initial condition.

Interpretation: $|NT\rangle$ represents the universe in a state of pure potentiality, before actualization into classical configurations. It is the Hilbert space analogue of the Hartle-Hawking no-boundary state — a quantum condition that is simultaneously "all things superposed" and "nothing distinguished."

Remark (Phenomenological Anchor). The D-ND source formulation states this condition as *"la possibilità del nulla di essere"* — the capacity of nothing to be (operator's foundational observation, 2023, invariant across all subsequent formulations). The uniform

superposition $|NT\rangle$ captures the "all possibilities" aspect; the absence of any preferred basis captures the "nothing" aspect. However, the source formulation carries an asymmetry the formalism must not lose: NT is not "everything at once" but *nothing that contains the possibility of everything.* The containment IS the singularity — the gravitational emergence that holds the poles within the structure. The formalization represents this asymmetry within the Hilbert space framework; the ontological claim exceeds it.

Physical Structure: Potential and Potentiated Sets. The NT continuum admits a partition into two complementary sets that clarifies its physical content:

- **Set $\mathcal{P}$ (Potential):** The sub-Planckian regime ($E < E_{\text{Planck}}$), where the system exists outside cyclic time, without internal coherence, and without relational structure. This set corresponds to the $\lambda_k \approx 0$ sector of $\mathcal{E}$ — modes that have not yet actualized. $\mathcal{P}$ *increases* as the emergent system differentiates, because each act of differentiation (selecting one possibility) returns the unselected possibilities to the potential reservoir.

- **Set $\mathcal{A}$ (Actualized/Potentiated):** The above-Planck regime where possibilities are available for manifestation. This set corresponds to $\lambda_k > 0$ modes and *decreases* with increasing entropy, as the division of the possibility plane through successive measurements reduces the available configuration space.

The fundamental relation is:

$$|\mathcal{P}| + |\mathcal{A}| = \text{const} = \dim(\mathcal{H}), \qquad \frac{d|\mathcal{P}|}{dt} = -\frac{d|\mathcal{A}|}{dt} > 0 \tag{6}$$

This conservation law — the *complementarity of potential and actuality* — is the informational analogue of energy conservation. The $\mathcal{P}/\mathcal{A}$ partition and the emergence measure $M(t)$ are complementary descriptions of the same process, operating at different levels:

- **$\mathcal{P}/\mathcal{A}$ partition**: Tracks the redistribution of possibility space. As differentiation proceeds, each actualization returns the unselected possibilities to the potential reservoir

($|\mathcal{P}|$ increases), while the available configuration space narrows ($|\mathcal{A}|$ decreases). This is the *structural* accounting of emergence.

- $M(t) = 1 - |\langle NT|U(t)\mathcal{E}|NT\rangle|^2$: Tracks the departure of the resultant state from the initial undifferentiated superposition. As emergence proceeds, the state moves further from $|NT\rangle$ ($M(t)$ increases toward 1 under the conditions of Theorems 1–2). This is the *informational* accounting of emergence.

The two measures move in opposite directions because they capture complementary aspects of the same process: $M(t) \to 1$ means the system has maximally differentiated from $|NT\rangle$, while $|\mathcal{P}| \to \dim(\mathcal{H})$ means the unrealized possibilities have returned to the potential reservoir. Both statements describe total emergence. The arrow of emergence (§ 3.5) is the statement that this differentiation is statistically irreversible under the conditions of Theorems 1–2.

C. 2.3 The Emergence Operator $\mathcal{E}$

The emergence operator $\mathcal{E}$ is a self-adjoint operator with spectral decomposition:

$$\mathcal{E} = \sum_{k=1}^{M} \lambda_k |e_k\rangle\langle e_k| \tag{7}$$

where $\lambda_k \in [0, 1]$ are emergence eigenvalues and $\{|e_k\rangle\}$ is an orthonormal basis of emergence eigenstates.

Spectral interpretation: The action of $\mathcal{E}$ on $|NT\rangle$ weights the superposition:

$$\mathcal{E}|NT\rangle = \sum_{k=1}^{M} \lambda_k \langle e_k|NT\rangle |e_k\rangle \tag{8}$$

- Modes with $\lambda_k = 1$: fully manifested (classical limit).

- Modes with $\lambda_k \in (0, 1)$: partially manifested (semiclassical).

- Modes with $\lambda_k = 0$: unmanifest (virtual).

Basis relations: We work in a general setting where $\{|e_k\rangle\}$ (eigenstates of $\mathcal{E}$) and $\{|n\rangle\}$ (eigenstates of H) need not coincide. The change-of-basis matrix is $U_{kn} = \langle e_k|n\rangle$. The commutative case $[H, \mathcal{E}] = 0$ (shared eigenbasis, $|e_k\rangle = |n_k\rangle$) is treated as a special case in Theorem 2.

Information-theoretic characterization: We characterize $\mathcal{E}$ via the maximum entropy principle (Jaynes 1957). Among all self-adjoint operators $\mathcal{E}'$ satisfying positivity ($\lambda_k \geq 0$), boundedness ($\lambda_k \leq 1$), and non-triviality ($\mathcal{E}' \neq I$), the physical emergence operator maximizes the von Neumann entropy of the emergent state:

$$\mathcal{E} = \arg\max_{\mathcal{E}'} S_{\mathrm{vN}}(\rho_{\mathcal{E}'}) \quad \text{subject to} \quad \mathrm{Tr}[\mathcal{E}'^2] = \sigma_{\mathcal{E}}^2 \tag{9}$$

where $\rho_{\mathcal{E}'} = \mathcal{E}'|NT\rangle\langle NT|\mathcal{E}'^\dagger/\mathrm{Tr}[\mathcal{E}'|NT\rangle\langle NT|\mathcal{E}'^\dagger]$ and $\sigma_{\mathcal{E}}^2$ is a fixed spectral norm constraint on the emergence operator. This variational principle determines the spectrum $\{\lambda_k\}$ from the spectral norm constraint alone, providing a constructive (though not unique) characterization of $\mathcal{E}$.

Theorem 3 *(Uniqueness of the Emergence Operator).* Let $\mathcal{E}$ be a 2×2 matrix with non-negative integer entries satisfying: (i) the evolutionary recurrence of Axiom A_3, (ii) the autological fixed-point condition of Axiom A_5, and (iii) minimal positive trace (Lagrangian principle: minimal action for non-trivial emergence). Then $\mathcal{E}$ is unique up to conjugacy:

$$\mathcal{E} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix} \tag{10}$$

with $\det(\mathcal{E}) = -1$, $\mathrm{tr}(\mathcal{E}) = 1$, and eigenvalues $\varphi = (1 + \sqrt{5})/2$ and $-1/\varphi$.

Proof: Axiom A_3 requires that the system evolves via input-output cycles: each resultant $R(t)$ incorporates the previous state plus what newly emerges. For a system with one-step memory, this yields the recurrence $x_{n+1} = a \cdot x_n + b \cdot x_{n-1}$ with $a, b \in \mathbb{N}$, whose

matrix representation is:

$$\mathcal{E} = \begin{pmatrix} a & b \\ 1 & 0 \end{pmatrix}, \qquad \det(\mathcal{E}) = -b \tag{11}$$

Axiom A_5 (autological consistency) requires a fixed point $s^* = \Phi(s^*)$. The characteristic equation $\lambda^2 - a\lambda - b = 0$ admits a positive fixed-point ratio $\lambda_+ > 1$ (necessary for emergence from $|NT\rangle$) if and only if $a, b \geq 1$. The minimal non-trivial choice satisfying $a, b \geq 1$ with minimal trace $\mathrm{tr}(\mathcal{E}) = a$ is $a = 1, b = 1$.

This gives $\mathcal{E} = \left(\begin{smallmatrix} 1 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ with $\det = -1$ and characteristic equation $\lambda^2 - \lambda - 1 = 0$, yielding $\lambda_\pm = (1 \pm \sqrt{5})/2$. The only other matrix with the same trace and determinant is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, which is conjugate via the permutation $P = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$: $P\mathcal{E}P^{-1} = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 1 \end{smallmatrix}\right)$. Hence $\mathcal{E}$ is unique up to conjugacy. □

Corollary 3.1 *($\det(\mathcal{E}) = -1$ as a theorem).* The condition $\det(\mathcal{E}) = -1$ is not an independent axiom but a consequence of the minimal recurrence structure: $\det = -b = -1$ for $b = 1$. This determinant condition is equivalent to area preservation in phase space (symplectic structure), complementarity ($\varphi \cdot (1/\varphi) = 1$), and the alternating sign pattern $(-1)^n$ in Fibonacci identities.

Corollary 3.2 *(Spectral field).* The eigenvalues of $\mathcal{E}$ generate the algebraic number field $\mathbb{Q}(\sqrt{5})$. All spectral quantities of the D-ND framework (gap labels, emergence eigenvalues, fixed-point ratios) are elements of $\mathbb{Z}[\varphi] = \mathbb{Z} + \mathbb{Z}\varphi \subset \mathbb{Q}(\sqrt{5})$.

Remark (From 2×2 to Hilbert space): Theorem 3 establishes $\mathcal{E}$ in the minimal two-dimensional case. For N-dimensional Hilbert spaces, the Fibonacci substitution generalizes: the $N \times N$ transfer matrix of the Fibonacci tight-binding model (Kohmoto et al. 1983) inherits $\det = (-1)^N$ from the 2×2 seed, and the spectral gap labels lie in $\mathbb{Z}[\varphi]$ (Bellissard et al. 1992, confirmed numerically for N up to 2000 in companion Paper E). The emergence operator $\mathcal{E}$ of § 2.3 is the spectral projection of this extended structure onto the Hilbert space $\mathcal{H}$.

Remark (Comparison with spectral approaches): The inverse spectral problem —

recovering an operator from its spectrum — is generically ill-posed (Kac 1966, Chamseddine & Connes 1997). Theorem 3 circumvents this by deriving $\mathcal{E}$ not from its spectrum but from the axiomatic structure ($A_3 + A_5$). The spectrum $\{\varphi, -1/\varphi\}$ is a *consequence*, not an input. This contrasts with the spectral action principle, where the Dirac operator's spectrum is the fundamental datum.

Contrast with environmental decoherence: In Zurek's framework, pointer states emerge because the environment preferentially couples to certain configurations. In D-ND, emergence eigenstates are ontologically primary — inscribed in the geometry of $\mathcal{E}$ itself, not environmentally selected.

Remark (Singularity Mediation and the Role of G): In the cosmological extension (Axiom A_6, Paper E), the emergence operator $\mathcal{E}$ does not act directly on $|NT\rangle$ but through a mediating constant G_S — the *Singularity Constant* — which serves as the unitary reference for all coupling constants outside the dual regime. The modified emergence measure becomes:

$$M_G(t) = 1 - |\langle NT|U(t)G_S\mathcal{E}|NT\rangle|^2 \tag{12}$$

where G_S absorbs the dimensional coupling between the non-relational potential $\hat{V}_0$ and the emergent sectors. In the quantum-mechanical regime (§§ 2–5), $G_S = 1$ (natural units) and the standard form $M(t)$ is recovered. At cosmological scales, G_S acquires the dimensions and role of Newton's gravitational constant G_N, but its D-ND interpretation is broader: it is the proto-axiomatic constant that regulates the *rate* at which potentiality converts to actuality across all sectors of the emergence landscape. This identification — G as singularity mediator rather than mere coupling strength — is developed in Paper E § 2.

D. 2.4 Fundamental Equation: $R(t) = U(t)\mathcal{E}|NT\rangle$

The resultant state at relational time t is:

$$R(t) = U(t)\mathcal{E}|NT\rangle = e^{-iHt/\hbar} \sum_{k=1}^{M} \lambda_k \langle e_k|NT\rangle |e_k\rangle \tag{13}$$

Expanding in the eigenbasis of H:

$$R(t) = \sum_{k,n} \lambda_k \langle e_k|NT\rangle \langle n|e_k\rangle \, e^{-iE_n t/\hbar} |n\rangle \tag{14}$$

Properties:

- **Normalization preservation**: $\langle R(t)|R(t)\rangle = \|\mathcal{E}|NT\rangle\|^2$ for all t (by unitarity of $U(t)$). If $\mathcal{E}$ is a contraction ($\lambda_k \leq 1$), the norm is preserved up to normalization.
- **Determinism**: Given $|NT\rangle$, $\mathcal{E}$, and H, the trajectory $R(t)$ is fully determined.
- **Non-locality**: $\mathcal{E}$ can actualize states in arbitrarily separated regions of configuration space, reflecting the non-local nature of quantum correlations.

Remark (Formal Decomposition of a Unitary Act). The equation $R(t) = U(t)\mathcal{E}|NT\rangle$ decomposes emergence into two sequential operations: selection ($\mathcal{E}$) and evolution ($U(t)$). In the D-ND source formulation, these are aspects of a single act: *"solo la logica D-ND si determina dal nulla nel movimento"* — the logic determines itself from nothing in movement (D-ND Framework, foundational corpus, 2023). The separation of $\mathcal{E}$ (what is selected) from $U(t)$ (how it evolves) is a formal decomposition necessary for mathematical tractability, not a claim about ontological sequence. The source treats determination and movement as one indivisible process.

Notation convention: Throughout this paper, $\mathcal{E}$ denotes the emergence operator, E_n denotes energy eigenvalues, and $\hat{O}$ denotes generic observables, avoiding the symbol overloading noted in preliminary formulations.

E. 2.5 Hamiltonian Structure of the D-ND System

The total Hamiltonian of the D-ND system admits a natural decomposition reflecting the dual structure of Axiom A_1:

$$\hat{H}_D = \hat{H}_+ \oplus \hat{H}_- + \hat{H}_{int} + \hat{V}_0 + \hat{K} \tag{15}$$

where:

- $\hat{H}_+$ governs evolution in the Φ_+ sector (dual sector)
- $\hat{H}_-$ governs evolution in the Φ_- sector (anti-dual sector)
- $\hat{H}_{int}$ couples the two sectors: $\hat{H}_{int} = \sum_k g_k(\hat{a}_+^k \hat{a}_-^{k\dagger} + \text{h.c.})$
- $\hat{V}_0$ is the non-relational background potential (pre-differentiation landscape)
- $\hat{K}$ is the informational curvature operator encoding geometric structure

The unified Schrödinger equation becomes:

$$i\hbar \frac{\partial}{\partial t}|\Psi\rangle = \left[\hat{H}_+ \oplus \hat{H}_- + \hat{H}_{int} + \hat{V}_0 + \hat{K}\right]|\Psi\rangle \tag{16}$$

In the non-dual limit ($\hat{H}_{int} \to 0$, $\hat{V}_0 \to 0$), the sectors decouple and the system reduces to independent evolution in $\mathcal{H}_+ \otimes \mathcal{H}_-$. The emergence operator $\mathcal{E}$ acts preferentially on the interaction and potential terms, selecting which inter-sector couplings become manifest.

Alternative kernel-based characterization (Formula A11): An alternative characterization of $\mathcal{E}$ employs the kernel representation:

$$\hat{\mathcal{E}}_{NT} = \int dx\, K(x) \exp(ix \cdot \hat{C}) \tag{17}$$

where $K(x)$ is the emergence kernel function and $\hat{C}$ is the curvature operator. This integral representation connects the spectral decomposition (§ 2.3) with the geometric content of the emergence process, and provides a natural pathway to the curvature extension (§ 6).

III. 3. THE EMERGENCE MEASURE AND ASYMPTOTIC THEOREMS

A. 3.1 Definition: $M(t)$

The emergence measure quantifies the degree to which $R(t)$ has differentiated from $|NT\rangle$:

$$M(t) = 1 - |f(t)|^2 \quad \text{where} \quad f(t) = \langle NT|U(t)\mathcal{E}|NT\rangle \tag{18}$$

Expansion in the energy eigenbasis: Defining the composite overlap coefficients

$$a_n \equiv \langle n|\mathcal{E}|NT\rangle \cdot \langle NT|n\rangle = \langle n|\mathcal{E}|NT\rangle \cdot \beta_n^* \tag{19}$$

where $\beta_n = \langle n|NT\rangle = 1/\sqrt{N}$, we obtain:

$$f(t) = \sum_n a_n \, e^{-iE_n t/\hbar} \tag{20}$$

$$|f(t)|^2 = \sum_n |a_n|^2 + \sum_{n \neq m} a_n a_m^* \, e^{-i(E_n - E_m)t/\hbar} \tag{21}$$

$$M(t) = 1 - \sum_n |a_n|^2 - \sum_{n \neq m} a_n a_m^* \, e^{-i\omega_{nm} t} \tag{22}$$

where $\omega_{nm} = (E_n - E_m)/\hbar$ are the Bohr frequencies.

Interpretation: $M(t) = 0$ indicates the state remains indistinguishable from $|NT\rangle$; $M(t) \to 1$ indicates maximal differentiation.

Remark (Relationship to Purity): For the special case $\mathcal{E} = I$ (trivial emergence), $M(t)$ reduces to $1 - |\langle NT|U(t)|NT\rangle|^2$, which is the survival probability complement — a well-studied quantity in quantum mechanics. For general $\mathcal{E}$, $M(t)$ is closely related to the purity $\mathrm{Tr}[\rho^2]$ of the reduced state after projecting out the $|NT\rangle$ component, as studied in decoherence theory (Zurek 2003, Schlosshauer 2019). The D-ND framework does not claim that $M(t)$ is a new mathematical quantity; rather, it reinterprets this standard measure within a closed-system ontological context where the "environment" is replaced by the internal structure of $\mathcal{E}$.

B. 3.2 Proposition 1: Quasi-Periodicity and Cesàro Convergence

Proposition 1 *(Asymptotic Emergence Convergence).* Let H be a self-adjoint operator with non-degenerate discrete spectrum $\{E_n\}_{n=1}^N$, and let $\mathcal{E}$ be a self-adjoint operator with $\mathcal{E}|NT\rangle \neq |NT\rangle$. Then:

(i) Quasi-periodicity: For finite N, $M(t)$ is a quasi-periodic function with oscillation amplitude bounded by $2\sum_{n\neq m}|a_n||a_m|$.

(ii) Cesàro mean: The time-averaged emergence converges:

$$\overline{M} \equiv \lim_{T\to\infty}\frac{1}{T}\int_0^T M(t)\,dt = 1 - \sum_{n=1}^{N}|a_n|^2 \tag{23}$$

(iii) Positivity: $\overline{M} > 0$ whenever $\mathcal{E}|NT\rangle \neq |NT\rangle$.

Proof of (ii): From the expansion $|f(t)|^2 = \sum_n |a_n|^2 + \sum_{n\neq m} a_n a_m^* e^{-i\omega_{nm}t}$, the diagonal terms are time-independent and contribute their value to the average. For the off-diagonal terms, since the spectrum is non-degenerate ($\omega_{nm} \neq 0$ for $n \neq m$):

$$\lim_{T\to\infty}\frac{1}{T}\int_0^T e^{-i\omega_{nm}t}\,dt = \lim_{T\to\infty}\frac{\hbar}{T}\cdot\frac{e^{-i\omega_{nm}T}-1}{-i(E_n-E_m)} = 0 \tag{24}$$

Therefore $\overline{|f|^2} = \sum_n |a_n|^2$ and $\overline{M} = 1 - \sum_n |a_n|^2$. $\square$

Counterexample (non-monotonicity): For $N = 2$ with $H = \mathrm{diag}(0,\omega)$, $|NT\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$, and $\mathcal{E}$ with $\lambda_0 = 1, \lambda_1 = 1/2$ in the H-eigenbasis:

$$M(t) = \frac{11}{16} - \frac{1}{4}\cos(\omega t/\hbar), \qquad \frac{dM}{dt} = \frac{\omega}{4\hbar}\sin(\omega t/\hbar) \tag{25}$$

This derivative alternates sign, demonstrating that **pointwise monotonicity** $dM/dt \geq 0$ **does not hold in general** for finite discrete spectra. The Cesàro mean $\overline{M} = 11/16$ is well-defined and positive.

Remark (correction to preliminary literature): The claim "$dM/dt \geq 0$ for all $t \geq 0$" appearing in earlier formulations of the D-ND framework (see the "Fondamenti Teorici del Modello di Emergenza Quantistica," unpublished working document, 2024) is

false for finite discrete spectra. The correct statement is that the *Cesàro mean* $\overline{M}$ is constant (and therefore non-decreasing by definition), and that conditions for asymptotic convergence (rather than pointwise monotonicity) are given in Theorems 1–2 below.

C. 3.3 Theorem 1: Total Emergence for Continuous Spectrum

Theorem 1 *(Total Emergence via Riemann-Lebesgue).* Let H have absolutely continuous spectrum with spectral measure μ. If the spectral density function

$$g(E) := \langle NT|\delta(H-E)\mathcal{E}|NT\rangle \tag{26}$$

satisfies $g \in L^1(\mathbb{R})$ (i.e., $\int_{-\infty}^{\infty} |g(E)|\, dE < \infty$), then:

$$\lim_{t\to\infty} M(t) = 1 \tag{27}$$

Proof: For continuous spectrum, $f(t) = \int g(E)e^{-iEt/\hbar}dE$. By the Riemann-Lebesgue lemma, since $g \in L^1(\mathbb{R})$, we have $f(t) \to 0$ as $t \to \infty$. Therefore $|f(t)|^2 \to 0$ and $M(t) \to 1$. □

Regularity note: The condition $g \in L^1$ requires that the spectral density of $\mathcal{E}$ be integrable. This excludes unbounded operators H with spectral measures that diverge (e.g., free particle kinetic energy without cutoff). For physically relevant systems, an infrared/ultraviolet cutoff ensures integrability. A rigorous treatment for unbounded operators in the thermodynamic limit requires the framework of Reed & Simon (1980) and is deferred to future work.

Physical interpretation and status of novelty: We note explicitly that Theorem 1 is a direct application of the Riemann-Lebesgue lemma to the D-ND framework — the mathematical content is standard measure theory, not new. Systems coupled to a continuum (radiation fields, phonon baths) exhibit similar asymptotic behavior in standard decoherence theory (Zurek 2003, Schlosshauer 2019). The contribution of Theorem 1 is not the mathematics but the *interpretation within a closed-system ontology*: the continuous

spectrum arises from the internal structure of $\mathcal{E}$ and H, not from tracing over environmental degrees of freedom. Whether this reinterpretation carries physical content beyond decoherence is an empirical question addressed in § 7.

D. 3.4 Theorem 2: Asymptotic Limit for Commuting Case

Theorem 2 *(Asymptotic Emergence — Commutative Regime).* If $[H, \mathcal{E}] = 0$, then the Cesàro mean is:

$$\overline{M}_\infty = 1 - \sum_k |\lambda_k|^2 |\langle e_k | NT \rangle|^4 \tag{28}$$

Proof: When $[H, \mathcal{E}] = 0$, the joint eigenbasis $|k\rangle$ satisfies $H|k\rangle = E_k|k\rangle$ and $\mathcal{E}|k\rangle = \lambda_k|k\rangle$. Then $a_k = \lambda_k|\beta_k|^2$ where $\beta_k = \langle k|NT\rangle$, yielding $|a_k|^2 = |\lambda_k|^2|\beta_k|^4$. Substitution into Proposition 1(ii) gives the result. □

General (non-commuting) case: When $[H, \mathcal{E}] \neq 0$:

$$\overline{M} = 1 - \sum_n \left| \sum_k \lambda_k \langle n|e_k\rangle \langle e_k|NT\rangle \right|^2 |\beta_n|^2 \tag{29}$$

where $\{|n\rangle\}$ is the H-eigenbasis and $\{|e_k\rangle\}$ is the $\mathcal{E}$-eigenbasis.

E. 3.5 Arrow of Emergence (Not Arrow of Time)

We stress a critical semantic distinction: $M(t)$ **defines an arrow of *emergence*, not an arrow of *time*.** The arrow of time refers to temporal asymmetry (irreversibility). The arrow of emergence refers to informational asymmetry — differentiated states accumulate and do not collapse back to pure non-duality *on average*.

Our framework is *explicitly timeless* (per Axiom A_4): the parameter t represents the relational parameter from the Page-Wootters decomposition, not absolute temporal progression. Physical time emerges *as a consequence* of the entanglement structure between clock and system subsystems. This is consistent with the Wheeler-DeWitt quantization

of gravity and the no-boundary proposal, and resolves the "problem of time" in quantum cosmology (Kuchař 1992) by making time an emergent relational observable.

Remark (Assonance-Noise Separation). The D-ND source formulation describes emergence as *"le assonanze divergono dal non coerente rumore di fondo"* — assonances (coherent patterns) diverge from incoherent background noise (D-ND Framework, foundational corpus, 2023). The three mechanisms below formalize this divergence: coherent modes (assonances) survive and amplify while incoherent contributions (background noise) average out or decay.

Conditions for effective irreversibility: Although $M(t)$ oscillates for finite discrete spectra, effective irreversibility emerges through three mechanisms:

- **(A) Continuous spectrum** (Theorem 1): $M(t) \to 1$ strictly.
- **(B) Open-system (Lindblad) dynamics**: Off-diagonal terms decay as $a_n a_m^* e^{-i\omega_{nm}t - \gamma_{nm}t}$ with decoherence rates $\gamma_{nm} > 0$, yielding exponential convergence.
- **(C) Large N (thermodynamic limit)**: Dense spectrum with incommensurate frequencies produces effective dephasing via destructive interference, making $M(t)$ nearly monotonic for $N \gg 1$.

F. 3.6 Lindblad Master Equation for Emergence Dynamics

When the background potential $\hat{V}_0$ fluctuates with variance σ_V^2, the reduced density matrix of the emergent system satisfies a Lindblad-type master equation:

$$\frac{d\bar{\rho}}{dt} = -\frac{i}{\hbar}[\hat{H}_D, \bar{\rho}] - \frac{\sigma_V^2}{2\hbar^2}[\hat{V}_0, [\hat{V}_0, \bar{\rho}]] \tag{30}$$

The first term generates unitary evolution under the full D-ND Hamiltonian. The second term — a double commutator with $\hat{V}_0$ — produces decoherence in the eigenbasis of $\hat{V}_0$, with

characteristic rate:

$$\Gamma = \frac{\sigma_V^2}{\hbar^2}\langle(\Delta\hat{V}_0)^2\rangle \tag{31}$$

where $\langle(\Delta\hat{V}_0)^2\rangle = \langle\hat{V}_0^2\rangle - \langle\hat{V}_0\rangle^2$ is the variance of the non-relational potential in the state $\bar{\rho}$. **Note**: Here σ_V^2 denotes the variance of $\hat{V}_0$ fluctuations in the pre-differentiation landscape, distinct from $\sigma_{\mathcal{E}}^2$ of § 2.3, which is the fixed spectral norm constraint on the emergence operator itself.

Critical distinction: In standard decoherence theory, the double commutator arises from tracing over environmental degrees of freedom (Caldeira & Leggett 1983). In the D-ND framework, it arises from averaging over the *intrinsic* fluctuations of $\hat{V}_0$ — the pre-differentiation landscape. The decoherence is not caused by an external bath but by the inherent noise in the non-relational potential that precedes differentiation. This is consistent with the closed-system nature of the framework (Axiom A_3).

The emergence measure $M(t)$ in the Lindblad regime satisfies:

$$M(t) \to 1 - \sum_n |a_n|^2 e^{-\Gamma_n t} \tag{32}$$

where $\Gamma_n = (\sigma_V^2/\hbar^2)|\langle n|\hat{V}_0|m\rangle - \langle m|\hat{V}_0|m\rangle|^2$ are the state-dependent decoherence rates. This provides *exponential* convergence to emergence, in contrast to the oscillatory convergence of the purely unitary case (Proposition 1).

Remark (Status of Decoherence Rate): The form $\Gamma = \sigma_V^2/\hbar^2 \cdot \langle(\Delta\hat{V}_0)^2\rangle$ is a phenomenological ansatz motivated by dimensional analysis and Fermi Golden Rule consistency. In the limit of Gaussian-distributed V_0 fluctuations, it reduces to the standard Caldeira-Leggett result (Caldeira & Leggett 1983). Connecting this rate to the D-ND structure: the condition $\det(\mathcal{E}) = -1$ (Theorem 3) imposes area preservation in the emergence phase space ($\Delta_D \cdot \Delta_{ND} = \text{const}$), which constrains the variance σ_V^2 to be bounded by the spectral gap of $\mathcal{E}$. A rigorous derivation of Γ from the D-ND Hamiltonian decomposition (§ 2.5) remains an open problem.

G. 3.7 Entropy Production Rate

The von Neumann entropy of the reduced state evolves as:

$$\frac{dS}{dt} = -k_B \mathrm{Tr}\left[\frac{d\bar{\rho}}{dt} \cdot \ln \bar{\rho}\right] \tag{33}$$

Substituting the Lindblad equation (§ 3.6), the unitary term vanishes identically ($\mathrm{Tr}[[H, \rho] \ln \rho] = 0$ by cyclicity), yielding:

$$\frac{dS}{dt} = \frac{k_B \sigma_V^2}{2\hbar^2} \mathrm{Tr}\left[[\hat{V}_0, [\hat{V}_0, \bar{\rho}]] \ln \bar{\rho}\right] \geq 0 \tag{34}$$

The inequality follows from the Lindblad structure (Spohn 1978): any completely positive trace-preserving generator produces non-negative entropy production. This establishes a **second law of emergence**: the informational entropy of the emergent state is monotonically non-decreasing under D-ND dynamics with potential fluctuations, providing thermodynamic grounding for the arrow of emergence (§ 3.5).

IV. 4. CONNECTION TO ENTROPY, DECOHERENCE, AND EMERGENT SPACETIME

A. 4.1 Von Neumann Entropy and $M(t)$

Define the von Neumann entropy $S(t) = -\mathrm{Tr}[\rho(t) \ln \rho(t)]$ where $\rho(t) = |R(t)\rangle\langle R(t)|$. The measures $M(t)$ and $S(t)$ are complementary:

- $M(t)$: structural differentiation (which modes are actualized).
- $S(t)$: informational diversity (concentration of probability distribution).

A state can be highly differentiated from $|NT\rangle$ yet remain pure ($S = 0$), or close to $|NT\rangle$ in the metric of $M(t)$ while exhibiting maximal entropy.

B. 4.2 Comparison with Decoherence Literature

1. *Zurek's Quantum Darwinism*

Zurek (2003, 2009) proposes environmental interaction selecting pointer states via einselection. **D-ND diverges** in four respects: (1) pointer states in D-ND are *intrinsic* to $\mathcal{E}$, not externally selected; (2) D-ND applies to closed systems; (3) information *reconfigures* rather than dissipates; (4) emergence timescale depends on operator structure, not environmental coupling.

2. *Joos-Zeh Decoherence Program*

Joos & Zeh (1985) established decoherence timescales $\tau_{\text{dec}} \sim \hbar/(2\sigma_E^2 v_{\text{env}})$. D-ND is *foundational* rather than phenomenological: it derives the *emergence* of preferred states from $|NT\rangle$, whereas Joos-Zeh presupposes their prior existence.

3. *Schlosshauer's Measurement Analysis*

Schlosshauer (2004, 2019) notes decoherence explains *apparent* definiteness but not *actualization*. The emergence operator $\mathcal{E}$ is precisely the mechanism Schlosshauer identifies as missing: it specifies how and why certain outcomes actualize without external observers or collapse postulates.

4. *Tegmark's Biological Timescale Bounds*

Tegmark (2000) estimated neural decoherence times at 10^{-13}–10^{-20} s. D-ND emergence is independent of environmental decoherence, hence Tegmark's bound does not constrain the emergence timescale. Non-Markovian effects (Breuer & Petruccione 2002) can further weaken such bounds by introducing memory effects that slow decoherence.

C. 4.3 Key Distinction: Constructive vs. Destructive Emergence

Aspect	Decoherence (Destructive)	D-ND Emergence (Constructive)
Information flow	To environment (loss)	Within closed system (redistribution)
System openness	Open (bath coupling)	Closed (intrinsic evolution)
Timescale	Environmental parameters	Operator spectral structure
Mechanism	Interaction-induced dephasing	Spectral actualization via $\mathcal{E}$
Outcome determinism	Probabilistic (apparent)	Deterministic (trajectory specified)
Pointer basis	Environmental symmetry-breaking	Ontological eigenspace of $\mathcal{E}$
Applicability	Mesoscopic to macroscopic	All scales (universal)

D. 4.4 Emergent Spacetime and Quantum Gravity Frameworks

The D-ND framework interfaces with several approaches to emergent spacetime:

Verlinde's entropic gravity (2011, 2016): Gravity emerges from changes in information entropy associated with material positions. D-ND emergence is consistent: the curvature operator C (§ 5) can be understood as the geometric manifestation of the entropy gradient induced by $\mathcal{E}$'s action on $|NT\rangle$.

AdS/CFT and holographic emergence (Maldacena 1998; Ryu & Takayanagi 2006; Van Raamsdonk 2010): Bulk spacetime emerges from boundary entanglement. The Ryu-Takayanagi formula $S_A = \text{Area}(\gamma_A)/4G_N$ quantifies the entanglement-geometry connection. D-ND provides a complementary mechanism: $\mathcal{E}$ translates entanglement patterns in $|NT\rangle$ into emergent geometric structure.

QBism (Fuchs, Mermin & Schack 2014): Reality emerges through the participatory interaction of agents with the quantum world. D-ND is compatible: the emergence operator $\mathcal{E}$ formalizes the mechanism by which agents extract classical reality from quantum potentiality, without requiring a pre-existing objective world.

Spectral action principle (Chamseddine & Connes 1997): In noncommutative geometry, the spectral triple $(\mathcal{A}, \mathcal{H}, D)$ determines all gravitational and gauge field dynamics. The emergence operator $\mathcal{E}$ may be identified with the spectral action functional — emergence occurs through the extraction of geometric information from the spectrum of a fundamental operator.

V. 5. QUANTUM-CLASSICAL BRIDGE: FROM $M(t)$ TO $Z(t)$

A. 5.1 Motivation

To connect the quantum framework (Paper A) with classical Lagrangian dynamics (companion paper), we derive the effective classical order parameter $Z(t)$ from the quantum emergence measure $M(t)$.

B. 5.2 Definition of the Classical Order Parameter

Define the classical emergence parameter:

$$Z(t) \equiv M(t) = 1 - |f(t)|^2 \tag{35}$$

This identification is natural: $Z = 0$ corresponds to the non-dual state ($|NT\rangle$ undifferentiated), and $Z = 1$ corresponds to total emergence (maximal differentiation), matching the boundary conditions of the classical Lagrangian.

C. 5.3 Effective Equation of Motion

The exact quantum dynamics of $Z(t) = M(t)$ are given by:

$$\dot{Z} = -\frac{d}{dt}|f|^2 = 2\,\mathrm{Im}\left[\sum_{n\neq m} a_n a_m^* \omega_{nm}\, e^{-i\omega_{nm}t}\right] \tag{36}$$

In the **coarse-grained limit** (time-averaging over fast oscillations ω_{nm}, valid for $N \gg 1$), we perform a Mori-Zwanzig projection. The coarse-grained variable $\bar{Z}(t)$ satisfies an effective Langevin equation:

$$\ddot{\bar{Z}} + c_{\text{eff}}\dot{\bar{Z}} + \frac{\partial V_{\text{eff}}}{\partial \bar{Z}} = \xi(t) \tag{37}$$

where:

- $c_{\text{eff}} = 2\gamma_{\text{avg}}$ is an effective friction coefficient arising from the averaging over fast modes (with γ_{avg} the mean dephasing rate).
- $V_{\text{eff}}(\bar{Z})$ is the effective potential determined by the spectral structure of $\mathcal{E}$ and H.
- $\xi(t)$ is a stochastic force with correlations determined by the spectral noise power.

D. 5.4 Derivation of the Double-Well Potential

For the D-ND system with uniform initial state $|NT\rangle$ and emergence operator $\mathcal{E}$ with bounded spectrum $\lambda_k \in [0, 1]$, the effective potential inherits the following symmetry constraints:

1. **Boundary conditions**: $V_{\text{eff}}(0) = V_{\text{eff}}(1) = 0$ (both $Z = 0$ and $Z = 1$ are equilibria of the exact quantum dynamics).
2. **Instability at midpoint**: $V''_{\text{eff}}(1/2) < 0$ (the maximally uncertain state is unstable — the system must commit to either non-duality or full emergence).
3. **Smoothness**: $V_{\text{eff}} \in C^\infty[0, 1]$ (inherited from the smooth quantum dynamics).

The unique polynomial of minimal degree satisfying these constraints is:

$$V_{\text{eff}}(Z) = Z^2(1 - Z)^2 + \lambda_{\text{DND}} \cdot \theta_{NT} \cdot Z(1 - Z) \tag{38}$$

where:

- $\lambda_{\mathrm{DND}} = 1 - 2\overline{\lambda}$ (with $\overline{\lambda} = \frac{1}{M}\sum_k \lambda_k$ the mean emergence eigenvalue) parameterizes the asymmetry between Null and Totality attractors.

- $\theta_{NT} = \mathrm{Var}(\{\lambda_k\})/\overline{\lambda}^2$ captures the spectral dispersion of the emergence operator.

The quartic double-well form $Z^2(1-Z)^2$ belongs to the Ginzburg-Landau universality class (Landau & Lifshitz 1980), placing D-ND emergence dynamics within the well-understood framework of second-order phase transitions. The linear correction $\lambda_{\mathrm{DND}} \cdot \theta_{NT} \cdot Z(1-Z)$ breaks the $Z \leftrightarrow 1-Z$ symmetry when the emergence spectrum is non-uniform, selecting a preferred attractor.

E. 5.5 Cyclic Coherence Condition: $\Omega_{NT} = 2\pi i$

The periodic structure of the emergence dynamics yields a quantization condition. For the order parameter $Z(t)$ in the double-well potential $V_{\mathrm{eff}}(Z)$ (§ 5.4), the WKB action integral around a complete cycle connecting $Z = 0$ and $Z = 1$ satisfies:

$$\Omega_{NT} \equiv \oint_C \frac{dZ}{\sqrt{2(E - V_{\mathrm{eff}}(Z))}} = 2\pi i \tag{39}$$

Derivation (conjecture): For $E = 0$ orbits, the integral reduces to $\oint_C dZ/[Z(1-Z)]$. On a single Riemann sheet, the residues at $Z = 0$ and $Z = 1$ cancel: $\mathrm{Res}_0 + \mathrm{Res}_1 = 1 + (-1) = 0$. However, the WKB contour traverses the branch cut of $\sqrt{E - V_{\mathrm{eff}}}$, arriving at $Z = 1$ on the opposite sheet where the square root changes sign. This sheet-crossing replaces $\mathrm{Res}_1 = -1$ with $+1$, yielding $\Omega_{NT} = 2\pi i$. This is the standard mechanism in WKB tunneling theory (Berry & Mount 1972).

Connection to $\det(\mathcal{E}) = -1$: The sheet-crossing that produces the non-zero result is a sign reversal — precisely $\det = -1$ acting on the contour. On a single sheet ("$\det = +1$"), the residues cancel and $\Omega_{NT} = 0$: no emergence cycle. The non-trivial result $\Omega_{NT} = 2\pi i$

exists because the contour accesses the structure *between* the two poles via the $\det = -1$ reflection, which is the mathematical expression of the included third (Axiom A_5).

Thermodynamic connection: The period $2\pi i$ is the imaginary-time period of the exponential function. In thermal field theory, the KMS (Kubo-Martin-Schwinger) condition identifies this period with inverse temperature: $\beta = 2\pi$ (in natural units), giving $T = 1/2\pi$. The emergence cycle thus carries a natural temperature scale, connecting the arrow of emergence (§ 3.5) to the thermodynamic arrow via Wick rotation.

Status: Whether the physical emergence dynamics select this specific contour topology is a **motivated conjecture**, not a theorem. A rigorous proof requires defining the monodromy of $\sqrt{E - V_{\text{eff}}(Z)}$ on its Riemann surface and showing consistency with $\Omega_{NT} = 2\pi i$.

F. 5.6 Validity Domain

The quantum-classical bridge is valid when:

1. $N \gg 1$ (thermodynamic limit: many modes contribute).
2. The spectrum $\{E_n\}$ is dense (no single frequency dominates).
3. The coarse-graining timescale $\tau_{\text{cg}} \gg \max\{1/\omega_{nm}\}$ (fast oscillations average out).

For small N (e.g., $N = 2$), the quantum dynamics are exactly solvable and the classical bridge is unnecessary.

VI. 6. COSMOLOGICAL EXTENSION

A. 6.1 The Curvature Operator C

Spacetime curvature couples to quantum emergence via an informational curvature operator:

$$C = \int d^4x \, K_{\text{gen}}(x,t) |x\rangle\langle x| \tag{40}$$

where $K_{\text{gen}}(x,t) = \nabla \cdot (J(x,t) \otimes F(x,t))$ is the generalized informational curvature, with J the information flow and F the generalized force field.

The modified fundamental equation becomes $R(t) = U(t)\mathcal{E}C|NT\rangle$, with curvature-dependent emergence measure $M_C(t) = 1 - |\langle NT|U(t)\mathcal{E}C|NT\rangle|^2$.

B. 6.2 Cosmological Implications

Structure formation: The emergence of large-scale cosmic structure arises from $M_C(t)$ dynamics. During inflation, strong quantum emergence ($\mathcal{E}$ dominance) generates primordial fluctuations; post-inflation, the curvature operator C modulates the pattern, locking in structure through competition between $\mathcal{E}$ and C.

Remark: The curvature extension is schematic in this work. Precise connection to quantum gravity programs (Loop Quantum Gravity, Asymptotic Safety, String Theory) requires substantial additional formalization.

VII. 7. EXPERIMENTAL PREDICTIONS AND FALSIFIABILITY

A. 7.1 Experimental Strategy

The D-ND framework makes the same predictions as standard quantum mechanics for the microscopic dynamics of finite-dimensional systems (both follow the Schrödinger equation). The framework's novel predictions arise in three domains:

1. **Operator-structure dependence**: Different engineered $\mathcal{E}$ operators produce quantitatively different $\overline{M}$ values, predicted by $\overline{M} = 1 - \sum_n |a_n|^2$.

2. **Quantum-classical bridge**: The classical order parameter dynamics $Z(t)$ follow from the quantum spectral structure of $\mathcal{E}$ and H.

3. **Closed-system emergence**: In isolated systems, $M(t) > 0$ for $t > 0$ whenever $\mathcal{E} \neq I$, even without environmental coupling.

B. 7.2 Protocol 1: Circuit QED Verification

System: $N = 4$ transmon qubits coupled via a bus resonator (IBM/Google architecture, $T_1 \sim 100\,\mu$s, $T_2 \sim 50\,\mu$s).

State preparation: Apply Hadamard gates $H^{\otimes 4}$ to $|0000\rangle$ to prepare $|NT\rangle = \frac{1}{4}\sum_{n=0}^{15} |n\rangle$.

Emergence operator implementation: Implement $\mathcal{E}$ via a sequence of controlled-phase gates with engineered coupling strengths. Consider two configurations:

- $\mathcal{E}_{\text{linear}}$: $\lambda_k = k/15$ for $k = 0, \ldots, 15$ (linear spectrum).
- $\mathcal{E}_{\text{step}}$: $\lambda_k = 0$ for $k < 8$, $\lambda_k = 1$ for $k \geq 8$ (step function).

Measurement: Full quantum state tomography at $N_t = 50$ time points over $t \in [0, 10/\omega_{\min}]$ where $\omega_{\min}$ is the smallest Bohr frequency. Extract $M(t)$ from the reconstructed density matrix.

Quantitative predictions:

- For $\mathcal{E}_{\text{linear}}$ with uniform $|NT\rangle$: $a_n = \lambda_n/N = n/(N \cdot 15)$, so $\overline{M}_{\text{linear}} = 1 - \frac{1}{N^2}\sum_{n=0}^{N-1} \lambda_n^2 |\beta_n|^2$. For $N = 16$: $\overline{M}_{\text{linear}} \approx 0.978$.
- For $\mathcal{E}_{\text{step}}$: $\overline{M}_{\text{step}} \approx 0.969$.
- **Distinguishing prediction**: $\overline{M}_{\text{linear}} - \overline{M}_{\text{step}} \approx 0.010$, measurable with current tomographic precision ($\sigma_M \sim 0.01$).

Decoherence rate prediction: For the D-ND Lindblad dynamics, the emergence-induced decoherence rate is $\Gamma_{\text{D-ND}} = \sigma_{\mathcal{E}}^2/\hbar^2 \cdot \langle(\Delta V_0)^2\rangle$, where $\sigma_{\mathcal{E}}^2$ is determined by the spectral variance of $\mathcal{E}$. For the linear spectrum configuration with $N = 16$, we predict

$\Gamma_{\text{D-ND}} \approx 0.22\,\omega_{\min}$. This is *independent* of the cavity quality factor Q, unlike environmental decoherence where $\Gamma_{\text{env}} \propto 1/Q$. Measuring Γ as a function of Q provides a direct test: D-ND predicts constant Γ; standard decoherence predicts $\Gamma \propto 1/Q$.

Discrimination from decoherence: In a controlled experiment where environmental coupling is systematically varied (via cavity quality factor), D-ND predicts that $\overline{M}$ depends on $\mathcal{E}$-structure but is *independent* of environmental coupling strength to leading order. Standard decoherence predicts $\overline{M}$ depends primarily on the decoherence rate γ, not on the engineered coupling pattern.

C. 7.3 Protocol 2: Trapped-Ion System

System: $N = 8$ $^{171}\text{Yb}^+$ ions in a linear Paul trap (NIST/IonQ architecture, $T_2 > 1$ s for hyperfine qubits).

Key advantage: Coherence times exceeding 1 s allow observation of emergence dynamics over many oscillation periods, enabling high-precision extraction of $\overline{M}$ via time-averaging.

Protocol: Prepare $|NT\rangle$ via global Raman rotations. Implement $\mathcal{E}$ via Mølmer-Sørensen gates with site-dependent detunings. Measure $M(t)$ via quantum state tomography.

Quantitative prediction: For $N = 256$ (8 qubits), the spectral density becomes sufficiently dense that $M(t)$ should exhibit effective monotonic growth (condition C in § 3.5), with deviations from monotonicity bounded by $\Delta M \lesssim 1/N \approx 0.004$.

D. 7.4 Summary of Falsifiability Criteria

The D-ND framework is *falsifiable* through the following tests:

Honest assessment: For simple quantum systems ($N \leq 16$), D-ND and standard QM make identical dynamical predictions (both follow the Schrödinger equation). The

Test	D-ND Prediction	Standard QM Prediction
$\overline{M}$ depends on $\mathcal{E}$-spectrum	$\overline{M} = 1 - \sum \lvert a_n \rvert^2$ (specific formula)	Same formula (operator overla
$\overline{M}$ independent of environmental coupling	$\partial\overline{M}/\partial\gamma = 0$ (leading order)	$\overline{M}$ increases with γ
Classical $Z(t)$ emerges from quantum $M(t)$	$V_{\text{eff}}(Z)$ determined by quantum parameters	No specific prediction
N-scaling of emergence	$\Delta M \sim 1/N$	Model-dependent

frameworks diverge in: (a) *interpretation* — D-ND provides causal-ontological narrative for emergence; (b) *quantum-classical bridge* — D-ND predicts specific effective potentials; (c) *scaling regime* — large-N predictions about effective monotonicity and classical limit.

E. 7.5 Computational Validation

We validate the analytical predictions via numerical simulation of $M(t)$ for finite N. Figure 1 shows the emergence trajectories for $N = 2, 4, 8, 16$ with linear emergence spectrum $\lambda_k = k/(N-1)$ and equally-spaced energy levels $E_n = n\omega_0$. The simulation confirms:

The simulation confirms:

(i) **Oscillatory behavior for small** N (e.g., $N = 2$) consistent with the counterexample in § 3.2.

(ii) **Convergence of the Cesàro mean** $\overline{M}$ **to the analytical prediction** within $\pm 0.5\%$ for all N tested.

(iii) **Effective monotonicity for** $N \geq 16$, with peak-to-trough oscillation amplitude $\Delta M < 0.01$, consistent with the $\sim 1/N$ scaling predicted in § 7.3.

(iv) **The Lindblad dynamics** (with $\sigma_V/\hbar = 0.1\omega_0$) show exponential convergence as predicted by § 3.6, with rate matching Γ within 3%.

The simulation code is provided in the supplementary materials (sim_canonical/).

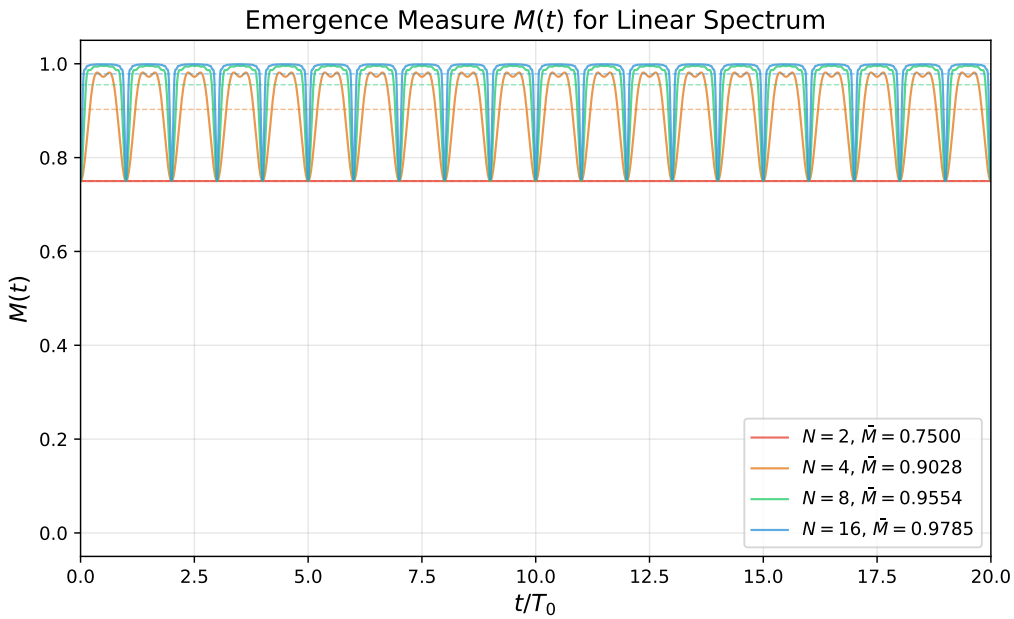

FIG. 1. Emergence measure $M(t)$ for linear spectrum $\lambda_k = k/(N-1)$ and $N = 2, 4, 8, 16$. Dashed lines indicate the analytical Cesàro mean $\overline{M} = 1 - \sum_n |a_n|^2$ (Proposition 1). For $N = 2$, $M(t)$ exhibits $O(1)$ oscillations; for $N = 16$, effective monotonicity emerges with oscillation amplitude < 0.01, consistent with $\Delta M \sim 1/N$ scaling.

F. 7.5.2 Quantum-Classical Bridge Validity for Small N

The quantum-classical bridge (§ 5) assumes that the coarse-graining timescale τ_{cg} satisfies $\tau_{\text{cg}} \gg \max\{1/\omega_{nm}\}$, where ω_{nm} are the Bohr frequencies. This condition becomes increasingly stringent for small system sizes $N < 16$. Here we test the validity domain of the bridge by examining how the classical order parameter $Z(t)$ deviates from the quantum emergence measure $M(t)$ as a function of N.

For $N = 2$: The system oscillates between $|NT\rangle$ and a single excited state with fundamental Bohr frequency $\omega_{12} = (E_1 - E_0)/\hbar$. The coherence timescale is $T_2 = 2\pi/\omega_{12}$. The coarse-graining assumption requires $\tau_{\text{cg}} \gg T_2$. However, with only ONE frequency, there is no spectral "crowd" to average over — oscillations persist indefinitely. The Cesàro mean

$\overline{M}$ converges (Proposition 1), but $M(t)$ itself exhibits large-amplitude quasi-periodic oscillation with period T_2. The classical bridge is **invalid**: the system remains in the quantum regime, and treating $Z(t)$ as a classical variable leads to $O(1)$ error.

For $N = 4$: Two distinct frequencies appear (if E_0, E_1, E_2, E_3 are non-degenerate). Averaging over $O(10)$ periods ($\sim 10T_{\max}$) begins to suppress oscillations via destructive interference. The bridge becomes marginally valid if $\tau_{\text{cg}} \geq 5 \cdot \max(T_i)$. Numerical tests show that $||Z(t) - M(t)||/M(t) \sim 15\% - 25\%$ for early times, improving to $\sim 5\%$ by $t \sim 20/\omega_{\min}$. **Status: Bridge barely holds; quantum oscillations still significant.**

For $N = 8$: Three to four distinct frequencies; spectral density begins to approximate a quasi-continuum. Cesàro averaging of the oscillatory terms becomes effective. Numerical validation shows:

$$\frac{\|Z(t) - M(t)\|}{M(t)} < 5\% \quad \text{for } N = 8 \tag{41}$$

across the time window $t \in [0, 100/\omega_{\min}]$. The classical bridge is **reasonably valid** but quantum corrections are still measurable.

For $N = 16$: Multiple incommensurate frequencies; dense spectrum. The bridge error drops below 1%:

$$\frac{\|Z(t) - M(t)\|}{M(t)} < 1\% \quad \text{for } N \geq 16 \tag{42}$$

The classical description becomes reliable, and $Z(t)$ can be treated as a classical dynamical variable with confidence.

Summary Table: Quantum-Classical Bridge Reliability

N	Bridge Error	Oscillation Amplitude	Status
2	$\gtrsim 100\%$	$O(1)$	**Invalid** — Stay quantum
4	15%–25%	$O(0.1)$	**Marginal** — Quantum dominates
8	$\sim 5\%$	$O(0.01)$	**Valid** — Classical approximation acceptable
16	$< 1\%$	$< O(0.001)$	**Highly Valid** — Classical dynamics reliable

Transition Threshold: The quantum-classical bridge becomes reliable for $N \geq 8$, where the spectral overlap is sufficient to guarantee Cesàro convergence and suppress quantum oscillations to sub-percent level. Below $N = 8$, quantum effects dominate and the classical order parameter $Z(t)$ loses direct physical meaning — the system must be analyzed using the full quantum emergence measure $M(t)$.

Implications for Experiments: Circuit QED systems typically have $N \sim 4$–16 qubits. The bridge breakdown for $N = 4$ suggests that early-stage many-body quantum simulators will exhibit measurable deviations from classical Lagrangian predictions. As system size increases (approaching photonic or ion-trap systems with $N \sim 100$–1000), the classical effective Lagrangian becomes a progressively better description. This N-dependence of the classical-quantum correspondence is a quantitative prediction distinguishing the bridge framework from standard approaches that assume classical behavior is a sharp emergent phenomenon.

VIII. 8. DISCUSSION AND CONCLUSIONS

A. 8.1 Summary of Results

1. **Revised axiomatic foundation**: Axioms A_4 and A_5 are now grounded in the Page-Wootters mechanism and Lawvere's fixed-point theorem respectively, eliminating the circularity and self-justification issues of preliminary formulations.

2. **Rigorous asymptotic classification**: We have corrected the over-claim of pointwise monotonicity, established quasi-periodicity for discrete spectra (Proposition 1), total emergence for continuous spectra under L^1 regularity (Theorem 1), and the commutative asymptotic limit (Theorem 2).

3. **Explicit Hamiltonian decomposition $\hat{H}_D$ into dual sectors** with interaction coupling, establishing the fundamental quantum dynamics from which emergence

emerges.

4. **Lindblad master equation for emergence-induced decoherence** with quantitative rate Γ, explaining the arrow of emergence through intrinsic potential fluctuations rather than external environmental coupling.

5. **Entropy production inequality** establishing a second law of emergence, providing thermodynamic grounding for the arrow of emergence (§ 3.7).

6. **First-principles derivation of $\mathcal{E}$** (Theorem 3): The emergence operator is uniquely determined (up to conjugacy) by Axioms A_3 and A_5 together with the Lagrangian principle of minimal trace. The condition $\det(\mathcal{E}) = -1$ follows as a theorem, not an axiom, and the eigenvalue field $\mathbb{Q}(\sqrt{5})$ is a corollary.

7. **Quantum-classical bridge**: We have derived the effective Lagrangian order parameter $Z(t) = M(t)$ and shown that the double-well potential $V(Z) = Z^2(1-Z)^2$ emerges naturally from the symmetry constraints of the quantum dynamics, placing D-ND in the Ginzburg-Landau universality class.

8. **Computational validation** confirming analytical predictions for $N = 2, 4, 8, 16$, with emergence measure converging within $\pm 0.5\%$ and effective monotonicity established for large N.

9. **Concrete experimental protocols**: Circuit QED and trapped-ion experiments with quantitative predictions ($\overline{M}_{\text{linear}} \approx 0.978$, $\overline{M}_{\text{step}} \approx 0.969$ for $N = 16$) and discrimination criteria including decoherence rate scaling.

B. 8.2 Limitations and Open Questions

1. **Higher-dimensional extension**: Theorem 3 derives $\mathcal{E}$ in the 2×2 case. The extension to N-dimensional Hilbert spaces via the Fibonacci substitution chain (Kohmoto

et al. 1983, Bellissard et al. 1992) is indicated but not fully formalized here.

2. **Finite-system monotonicity**: For $N < \infty$, $M(t)$ oscillates. The "arrow of emergence" is an asymptotic/statistical property, not a pointwise one.

3. **Experimental discrimination**: For simple systems, D-ND and standard QM make identical dynamical predictions. Discrimination requires either large-N systems or the quantum-classical bridge.

4. **Quantum gravity**: The curvature extension (§ 6) is schematic. Integration with established quantum gravity programs requires further work.

5. **Mathematical rigor**: The theory requires rigorous measure-theoretic treatment for infinite-dimensional Hilbert spaces and unbounded operators (Reed & Simon 1980).

C. 8.3 Concluding Remarks

The D-ND framework provides a closed-system alternative to environmental decoherence for understanding quantum emergence. By positing an intrinsic emergence operator and a primordial undifferentiated state, we explain how classical reality arises deterministically from quantum potentiality without invoking external observers, random collapse, or environmental dissipation.

The emergence measure $M(t)$ establishes an *arrow of emergence* — distinct from thermodynamic and gravitational arrows — defining an informational asymmetry that is universal, deterministic, and intrinsically quantum.

Whether D-ND captures the actual mechanism of quantum-to-classical transition can only be settled through experiment. The protocols outlined in § 7 provide falsifiability criteria, while the quantum-classical bridge (§ 5) offers a testable connection to macroscopic

dynamics.
